

Security Tools

Multi Factor Authentication: A process that a user provides two (2-Factor Authentication) or more layers of security to access the account. Typically something like the Google authentication app, could be via SMS, or even biometric. This helps when a users password is compromised in hopes the attacker doesn't have access to the users MFA. From what I saw, the only time MFA isn't effective is when the attacker has the 'token' of the account, its found in the cookies of the browser and that's basically a hard key to get in the account.

Shields Up: A service that checks if ports are closed or open, evaluates firewall and highlights vulnerabilities. This is used to attempt to increase the security of the network.

Firewall: Controls traffic to the computer. The user sets the rules for the firewall, then the firewall monitors based on those rules. If the firewall doesn't like the packet it sees it will block the traffic of that network. This prevents unauthorized access to the network.

Whols: Checks for authentication in a domain, this means itll check ownership, DNS, and IP information. This helps users make a choice if a domain is legit and not malicious.

Authentication: Verifies identity before access is granted. Ensuring the security of data. This could be in the form of passwords, biometrics, tokens, and MFA. This is a fundamental of cyber security overall, because this is used on every single website you have an account on.
